Submitted February 20, 2014; final revision received July 23, 2014; accepted August 7, 2014.

Plantar fasciitis, a chronic degenerative process that causes medial plantar heel pain, is responsible for approximately 1 million physician visits each year. Individuals with plantar fasciitis experience pain that is most intense during their first few steps of the day or after prolonged standing. The authors provide an overview of the diagnosis and management of a common problem encountered in the primary care setting. Routine imaging is not initially recommended for the evaluation of plantar fasciitis but may be required to rule out other pathologic conditions. Overall, plantar fasciitis carries a good prognosis when patients use a combination of several conservative treatment modalities. Occasionally, referral to a specialist may be necessary.

**Anatomy**

The plantar fascia comprises 3 bands of dense connective tissue, which originate at the medial tubercle of the calcaneus and fan distally to insert into the base of each proximal phalanx (Figure 1). First described by Hicks in 1954 as the windlass mechanism, the plantar fascia tenses during the terminal stance to toe-off phases of gait. This tension elevates and reinforces the medial longitudinal arch, which in turn allows the foot to function as a rigid lever for forward propulsion.

**Pathophysiology**

Plantar fasciitis is a chronic degenerative process involving the plantar aponeurosis of the foot, most commonly at its insertion into the medial tubercle of the calcaneus. The process involves repetitive strain that seems to cause microtearing, which induces a repair response. Histologic analysis demonstrates marked thickening and fibrosis of the plantar fascia along with collagen necrosis, chondroid metaplasia, and calcification. Although plantar fasciitis has historically been assumed to be primarily an inflammatory process, these findings suggest a principally degenerative mechanism, leading some authors to suggest that plantar fasciosis may be a more histologically accurate term.

**Epidemiology**

Each year approximately 1 million office-based physician visits result in a diagnosis of plantar fasciitis. Most patients initially seek care from their primary care physician. The peak incidence of plantar fasciitis occurs in persons aged between 45 and 64 years, and it is more common among women. Other at-risk populations...
include persons with flat (planus) or high-arched (cavus) feet, long-distance runners, military personnel, persons with occupations requiring prolonged standing, and persons who are obese or sedentary. Up to one-third of patients may present with bilateral plantar fasciitis.

Diagnosis

Clinical Evaluation
Plantar fasciitis is primarily a clinical diagnosis. Patients classically describe medial plantar heel pain on weight bearing, which is often most intense during their first few steps in the morning but tends to improve with rest. This pain may progress over the course of the day, especially after prolonged standing. Acute exacerbations may occur at any time when rising from a seated position. Physicians should look for other risk factors for plantar fasciitis and assess the appropriateness of the patients’ footwear choices for their customary activities.

A thorough musculoskeletal examination of both lower extremities should be performed. Classic physical examination findings suggestive of plantar fasciitis include reproducible pain with palpation of the plantar medial aspect of the heel and pain with passive dorsiflexion of the ankle and toes (windlass test). A contributing planus or cavus foot deformity may be noted. Ankle range of motion should also be assessed. Active dorsiflexion less than 10° beyond neutral is indicative of an equinus contracture.

The Table summarizes the distinguishing historical and physical examination findings of other items in the differential diagnosis of plantar fasciitis.

Imaging
Diagnostic imaging is not recommended for the initial evaluation of plantar fasciitis. However, magnetic resonance images, triple-phase bone scans, or other imaging results may be required to rule out other considerations in the differential diagnosis, particularly when 4 to 6 months of nonsurgical treatment has failed or when the patient presents with atypical heel pain (Table).

Treatment

Nonsurgical
Approximately 85% to 90% of patients with plantar fasciitis can be successfully treated without surgery. Methods include rest, over-the-counter (OTC) nonsteroidal anti-inflammatory drugs (NSAIDs), stretching, counterstrain technique, orthoses, corticosteroid injections, extracorporeal shock wave therapy (ESWT), and ultrasound therapy.

Although treatment may be required for 6 months or longer, 80% of patients treated conservatively have no long-term recurrence of pain. Current recommendations for the conservative management of plantar fasciitis call for a multimodal, evidence-based approach.

Initial treatment should include sufficient foot rest with conservative analgesic use. Over-the-counter NSAIDs have been shown to be an adequate means of pain control when used in combination with other forms of treatment. Focused stretching of the Achilles tendon, plantar fascia, and intrinsic muscles of the foot has also been dem-

EVIDENCE-BASED CLINICAL REVIEW

Approximately 85% to 90% of patients with plantar fasciitis can be successfully treated without surgery.

with chronic plantar fasciitis. The suspected therapeutic mechanism of night splinting is the maintenance of ankle dorsiflexion and toe extension, creating a constant mild stretch on the plantar fascia, presumably allowing it to heal at a functional length.

Corticosteroid injections should be considered with caution, owing to a potentially unfavorable risk-benefit ratio for patients with plantar fasciitis. In a ran-

The intermittent application of ice seems to provide some benefit to patients with plantar fasciitis when compared with heat application.

The osteopathic manipulative treatment technique of counterstrain may provide immediate improvement of plantar fasciitis symptoms; however, maintenance of these results has not been documented, to the authors’ knowledge. The plantar fascia should be placed in a position of least resistance with passive flexion of the knee and plantar flexion of the ankle and toes. This position should be maintained for approximately 90 seconds while monitoring the tenderpoint, which is most commonly located at the plantar fascial insertion on the medial calcaneus. The foot should then be returned to a neutral position and reassessed.

A wide variety of orthosis options are available for the management of plantar fasciitis. The use of shoe inserts (eg, silicone heel pads, felt pads, and rubber heel cups) in combination with stretching exercises has been shown to provide superior short-term improvement in heel pain compared with stretching alone. A randomized, controlled study comparing OTC shoe inserts with customized shoe inserts found no significant difference in pain relief between the 2 groups at 12-month follow-up. Regardless, the long-term efficacy of shoe inserts for plantar fasciitis is uncertain. The use of posterior-tension night splints has also shown benefit in patients

domized, prospective clinical trial, corticosteroid injections provided better relief of plantar fasciitis symptoms at 1 month but not at 6 months when compared with control groups. The risks associated with corticosteroid injection include skin and fat pad atrophy, infection, and plantar fascia rupture. In a retrospective study, corticosteroid injections were associated with a 10% incidence of plantar fascia rupture. This complication can be serious, possibly leading to problems associated with the loss of the medial longitudinal arch of the foot.

There are limited data available regarding ESWT for the management of plantar fasciitis. Its therapeutic mechanism is unknown. Nonetheless, in a randomized, double-blinded clinical trial, the addition of 1 application of 3800 high-energy shock waves to standard therapies demonstrated a statistically significant improvement in symptoms at 3 months compared with standard therapies without ESWT.

Ultrasound therapy has recently been investigated for the management of refractory plantar fasciitis. Although there is presently insufficient evidence to support its efficaciousness, studies suggest it is relatively safe.

**Surgical**

Partial or complete plantar fasciotomy is indicated only after at least 6 to 12 months of conservative treatment has failed. Before proceeding with surgery, the differential diagnosis must be revisited to consider other causes of subcalcaneal pain (Table). Surgical release of greater than 40% of the plantar fascia may have detrimental effects on other ligamentous and bony structures in the foot. Nevertheless, Davies and colleagues reported that 75% of patients who underwent surgical intervention after failed conservative treatment reported substantial or complete reduction in heel pain.

**Suggested Treatment Plan**

Conservative treatment should first be initiated (Figure 2). Patients should limit activity by level of tolerance and modify footwear (eg, avoid flip-flops and sandals, use OTC shoe inserts). Also, a plantar fascial stretching regimen should be initiated, as follows:

- **Wall push:** With the heel on the ground and ball of foot on the base of a wall, the patient leans into the wall to stretch the plantar fascia for at least 2 minutes at 10-second intervals on the affected side at least 2 times daily. (The condition will improve much more rapidly if the patient can do 3 sets of wall pushes every hour on the hour.)
- **Towel pick-up:** With the toes of the affected foot, the patient picks up a dry paper towel, drops it, and repeats for 2 minutes once daily in the evening.
- **Ice roll:** The patient rolls the foot over the top of a frozen water bottle for 2 minutes once daily in the evening.
Outcomes with home stretching alone are excellent after treatment for half the amount of time that symptoms have been present. For example, symptoms present for 1 year would get good results after 6 months of treatment.

If conservative treatment is not effective, moderate treatment consisting of custom orthoses, night splints, and judicious use of injection therapy should be tried. If moderate measures fail, if the symptoms have lasted more than 1 year, and if the patient has been fully compliant with the multiple daily stretching routine, surgery may be required.

Summary
The plantar fascia is subject to chronic repetitive stress at its origin, and plantar fasciitis is one of the most common causes of heel pain. The diagnosis is often made clinically based on the location of pain at the medial calcaneal tubercle. Risk factors include age, female sex, obesity, prolonged weight bearing, and repetitive activities that cause strain on the plantar fascia. Imaging may be necessary to rule out other causes of heel pain in the differential diagnosis after nonsurgical treatment has failed or after the patient presents with atypical pain.

A combination of conservative treatments is successful in most cases and should include NSAIDs, a proper stretching regimen, night splints, and, if there is no relief after 6 to 12 months, referral to a specialist. Short-term relief may be provided by OMT and foot orthoses, but there is no evidence of these modalities providing long-term improvement. Surgical treatment should only be considered if all other methods fail.

Author Contributions
Dr Thompson, Student Doctor Saini, and Drs Reb and Daniel provided substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; drafted the article or revised it critically for important intellectual content; and gave final approval of the version of the article to be published.
